Diagnostic Hysterolaparoscopy in the Evaluation of Female Factor Infertility: A Cross-sectional Study at a Tertiary Care Hospital in Central India

Prashanthi Selvaraj¹, Moushmi Parpillewar², Juzar Fidvi³

ABSTRACT

Background: Infertility is a worldwide problem affecting people of all geographical location and socioeconomic status. It is estimated that globally 60–80 million couples suffer from infertility every year. The main objective of the study is to detect the diagnostic efficacy of hysterolaparoscopy in evaluating the tubal, uterine, ovarian, and pelvic pathologies causing infertility and also compare the findings of a hysterosalpingogram with diagnostic laparoscopy in evaluating the tubal factor infertility.

Materials and methods: This hospital-based cross-sectional study included an evaluation of 1,456 couples presenting with complaints of infertility at the Outpatient Department of Government Medical College, Nagpur during the period of February 2016 to September 2018. After thorough gynecological examination and investigations, 130 infertile women were posted for diagnostic hysterolaparoscopy. All the data were collected on predesigned proforma and the results were tabulated and raw percentages calculated to describe the results.

Results: Among the 130 infertile women, 102 women (78.46%) had primary and 28 (21.53%) had secondary infertility. The maximum number of patients belonged to the age group of 26–30 years (39.23%). About 56% of patients were in the active marriage life of 3–5 years duration. Most of them had multiple factors affecting their fertility. Out of the 130 infertile women, 32 patients (24.62%) had uterine factors, 44 patients (33.84%) had peritoneal factors, 67 patients (51.5%) had ovarian factors, and 89 patients (68.46%) had tubal factors. Only eight patients (6.15%) had normal findings in laparoscopy. Out of the 130 patients, 122 (93.84%) had more than one factor causing infertility. About 26.15% of patients had positive findings in diagnostic hysterolaparoscopy.

Conclusion: Hysterolaparoscopy provides both a panoramic view of the pelvic reproductive anatomy and also a magnified view of the pelvic organs and peritoneal surfaces. It is generally regarded as the most reliable tool in the diagnosis of tubal pathology and other intra-abdominal causes of infertility because of the correctable abnormalities like endometriosis, adnexal adhesions, and septate uterus which are usually missed, are usually identified that helps in formulating a specific plan of management.

Keywords: Diagnostic laparoscopy, Hysteroscopy, Infertility.

INTRODUCTION

The World Health Organization defines health as a state of complete physical, mental, and social well-being and not merely the absence of disease. By this definition, infertility is a major cause of diminished health in both developing and developed countries.¹ The prevalence of infertility ranged from 3.5 to 16.7% in developed and 6.9 to 9.3% in developing nations.² Before the advent of hysterosalpinography, infertility was usually attributed to female factor infertility from 10 to 3.5%.³ This study was undertaken to evaluate the diagnostic efficacy of hysterolaparoscopy in the comprehensive evaluation of female factor infertility: A Cross-sectional Study at a Tertiary Care Hospital in Central India. Int J Infertil Fetal Med 2020;11(2):37–41.

Diagnostic Hysterolaparoscopy in the Evaluation of Female Factor Infertility

Materials and Methods
This study is a hospital-based cross-sectional study done at a tertiary care center in Central India, done from February 2017 to September 2019 for a period of 18 months. A total of 1,456 infertile couples attending the infertility clinic at Government Medical College, Nagpur were recruited in the study. The screening tests included ultrasonography (USG) of the pelvis, semen analysis, HSG, Chlamydia antibody testing, thyroid function test, and hormonal testing, in selected patients. Out of them, 130 infertile women were recommended diagnostic hysterolaparoscopy as the next line of investigation in their infertility workup, and findings were recorded in a structured proforma.

Primary Objective
To find out the role of diagnostic hysterolaparoscopy in the evaluation of different factors causing female infertility and the feasibility of providing therapeutic management concurrently.

Secondary Objective
To compare the findings of HSG with findings on diagnostic laparoscopy with chromopertubation in the evaluation of tubal factor infertility.

Inclusion Criteria
- Women with primary and secondary infertility.
- Women with failed ovulation induction in three cycles.
- Abnormal HSG findings.

Exclusion Criteria
- Medical disorders are a contraindication for anesthesia.
- Active pelvic infection.
- Couple with any psychosexual dysfunction.
- Couple under any kind of substance abuse.

Detailed history, physical examination, basic endocrinological investigations, USG pelvis (preferably transvaginal), HSG, and semen analysis were done before the procedure. Hysterolaparoscopy was done under appropriate anesthesia between days 9 and 12 of the menstrual cycle. Chromopertubation was carried out in all cases to test the patency of the tube under laparoscopic vision by using 15 mL of 0.5% methylene blue dye.

Statistical Analysis
Data were coded and analyzed in statistical software, STATA version 10.1, 2011. Descriptive statistics included summary measures like mean and standard deviation for quantitative variables and frequency, percentages for categorical variables.

Results
The demographic parameters are given in Table 1. Out of the 130 women, 102 (78.4%) had primary infertility and 28 (21.53%) had secondary infertility. Female factor infertility accounted for 91 cases (70%), male factor in 13 cases (10%), both in 19 cases (14.6%), and unexplained infertility in 7 cases (5.38%) (Fig. 1). Nearly 56% reported at our infertility clinic was in the active marriage life of 3–5 years, while only about 3% of couples had infertility of >12 years (Fig. 2). Out of the 130 patients, 67 patients (51.5%) had ovarian findings on laparoscopy, tubal factors were seen in 89 patients (68.46%), 55 patients (42.30%) had peritoneal factors, and 21 patients (16.15%) had uterine factors (Fig. 3). Many patients had more than one factor responsible for their infertility which was diagnosed by laparoscopy. Out of 130 patients, no abnormality was found in 7 patients (5.38%) and all four factors were found in 1 patient (0.77%).

A tubal factor was the most commonly encountered abnormality in laparoscopy.Diagnostic hysterolaparoscopy was done in all cases along with diagnostic laparoscopy. Out of the 130 patients, 96 cases (78.85%) had no abnormality in hysteroscopy. Septate uterus (13 cases, 10%) was the most common abnormality. Various therapeutic interventions were done in selected patients during diagnostic laparoscopy (Fig. 4) and hysteroscopy (Fig. 5). Polycystic ovarian drilling was the most common therapeutic procedure attempted through laparoscopy and septum resection through hysteroscopy. Out of the 130 cases subjected to both HSG and laparoscopy, there was a difference in findings between HSG and chromopertubation in 40 cases (30.77%). Only in about 90 cases (69.23%), the findings of HSG correlated with laparoscopy. Hence, tubal factor infertility cannot be confirmed with HSG alone. Diagnostic laparoscopy with chromopertubation can be done in cases where tubal factor has been ruled out with HSG but still conception has not occurred for more than three cycles. A more interesting observation was that when these two modalities were combined then the diagnostic accuracy reached 100%. This reinstated the age-old theory that HSG and laparoscopy are complementary and not supplementary in diagnosing tubal factor of infertility. Calculating the sensitivity, specificity, and validity of HSG is well beyond the scope of this study.

DiscusSion

Exploration of the female genital tract is one of the essential elements of infertility assessment. Laparoscopy provides both a panoramic view of the pelvic reproductive anatomy and a magnified view of the peritoneal surfaces. It is generally regarded as the most reliable tool in the diagnosis of tubal pathology and other intra-abdominal causes of infertility. About 96% of women in our study were aged 20–35 years, thus supporting the fact of early marriage and childbearing in developing countries. This is in contrast to the current trend in developed as well as developed countries to some extent to defer childbearing until the mid-30s, which results in a diminished time frame available both for conception and for infertility evaluation. The predominance of a female factor was seen in both primary and secondary infertility, but the female factor was significantly higher in secondary infertility than in primary infertility. This was explained by Ngowa et al., where they suggested that pelvic infection resulting from ascending infection during childbirth can lead to tubal damage and thus higher contribution to the incidence in the female factors in secondary infertility.

Infertile women with normal ovulation, pelvic ultrasound findings, hormonal profile, and husband semen analysis have a higher possibility of tubo-peritoneal pathologies like endometriosis (Fig. 6). Performing hysterolaparoscopy as a ‘one-step procedure’ in these women will be more beneficial. There could be more than one cause of infertility in a patient and it becomes equally important to diagnose each cause as each individual cause need specific and complete treatment. In our study, an effort was made to find out the role of diagnostic hysterolaparoscopy in evaluating the different factors responsible for female infertility and providing therapeutic management wherever feasible. The secondary objectivity of this study is to compare the findings of HSG with diagnostic laparoscopy and chromopertubation in evaluating the tubal factor of female infertility. On analyzing the type of infertility in our study, out of 130 couples, primary infertility was seen in 78.46% and secondary infertility was 22% which was very similar to the famous study of Duignan et al. The various causes causing female infertility were broadly categorized into ovarian, tubal, uterine, peritoneal, and cervical factors. Other causes like implantation failure, autoimmune disorders, psychological problems, and maturation defects of the...
gametes were not evaluated and were well above the limits of our study.

In our study, we found that tubal factor causing infertility was present in 68.46%, ovarian factor in 51.5%, uterine factor 24.61%, and peritoneal factor was present in 33.84% cases. Only 1 case (0.77%) of cervical factor infertility was documented. The results of other studies are shown in Table 2. There is significant variation in the percentage of various factors causing infertility in our study compared with the other studies, but one point has been common despite this variation that, there is a predominance of a female factor of infertility over all other factors individually. One hundred and twenty-two patients (93.84%) out of 130 had more than one abnormality in laparoscopy. We noted in our study that the majority of patients were suffering from tubal factor infertility. Tubal appearance on laparoscopy was further subdivided into five different subcategories as beading of tubes, phimosis, hyperemia, hydrosalpinx, and lead pipe appearance, their impact on infertility was not known. Patency of the tube was assessed with chromopertubation during a diagnostic laparoscopy.

Not only our study but also every study we reviewed showed a marked preponderance of tubal blockage (unilateral or bilateral) as the most important factor for infertility. The majority of patients with ovarian factor infertility had polycystic ovarian syndrome (PCOS) 34 patients (26.15%) (Fig. 7). Other causes of ovarian infertility in our study were ovarian cyst, low ovarian reserve with small or streak ovaries, and premature ovarian insufficiency. All the studies reviewed, demonstrated the dominance of PCOS in an ovarian factor of infertility. In our cases, 32 cases (24.61%) contributed to uterine factors. The main cause of uterine factor infertility was uterine fibroid 11 cases (34.3%). Three major causes of peritoneal factor infertility were endometriosis, pelvic adhesions, and pelvic tuberculosis in our study. There were a total of 44 cases (33.8%) out of which 21 cases (47.7%) had endometriosis and 19 cases had pelvic adhesions (43.18%). There were 4 cases (9.09%) of pelvic tuberculosis with dense peritoneal adhesions and tubo-ovarian mass, later confirmed with biopsy for granuloma. Most of the studies showed the dominance of endometriosis in the peritoneal factor of infertility, which was similar to our study. There was only 1 patient with cervical stenosis.

In our study, out of the 122 patients who were detected with abnormality through diagnostic laparoscopy, in 50 (38.46%) patients therapeutic interventions were done in the same sitting. Out of the 11 patients diagnosed with fibroid uterus, 7 patients underwent myomectomy and 24 patients had PCOS drilling. Out of the 10 patients with an ovarian cyst, 7 patients underwent laparoscopic ovarian cystectomy. Other procedures like adhesiolysis, chocolate cyst drainage, and fimbrial dilatation were also done. We found in our study that, out of the 130 patients, only 90 patients (69.23%) had similar findings of tubal patency on HSG and laparoscopic chromopertubation. The rest of the 40 patients had different results when their tubal patency was checked with chromopertubation. Therefore, the concordance between HSG and diagnostic laparoscopy was found out to be 69.23%. This explains why HSG is only considered as a complementary investigation for tubal patency and not a substitution for laparoscopy.

In all patients, hysteroscopy was done along with diagnostic laparoscopy. Out of the 130 cases, 34 patients (26.15%) had abnormalities. The most common finding on hysteroscopy was complete septum of the uterine cavity seen in 7 patients (20.5%), followed by subseptate uterus in 6 patients (17.64%). Other findings were submucous fibroid, endometrial polyp, and cavity adhesions. The therapeutic intervention was done in selected

</table>
patients in the same or subsequent sitting. In 32 patients (24.16%),
the hysteroscopic therapeutic intervention was done. The most
common procedure done was septal resection in 13 patients
(40.62%) and submucous fibroid removal in 7 patients (21.87%).
Other procedures like polyp removal, metroplasty, adhesiolysis,
and tubal cannulation for the proximal tubal block were also done.
Although a diagnosis of septate uterus per se is not an indication
for septoplasty, many studies quoted their reproductive
performance with an uncorrected septum is poor (80% pregnancy
loss, 10% preterm delivery, 10% term delivery). Apart from the
septate uterus, other uterine anomalies (Fig. 8) like bicornuate (2
cases) and unicornuate (4 cases) uterus were best diagnosed with
hysterolaparoscopy.

Diagnostic hysterolaparoscopy is a very safe procedure.
Other than mild abdominal pain, there were no major surgical or
anesthetic complications in any of our patients.

In our study, the incidence of a male factor was only 10%. This
percentage seems to be less when compared to other studies
(Table 2). This is because, for any couple with primary male factor
infertility, found in semen analysis, intrauterine insemination (IUI)
was the first line of management along with ovulation induction
after tubal factors were ruled out by HSG. Severe male factor
infertility patients were referred to an andrologist for evaluation
and treatment. These female patients were deferred diagnostic
laparoscopy, until three cycles of failed IUI. This is a selection bias
in our study.

**Conclusion**

The results of our study suggest that diagnostic laparoscopy is the
most useful procedure in the infertility workup. The different
factors of infertility are thoroughly evaluated through laparoscopy,
especially the peritoneal factors of which contributed to a large
group of patients in our study, who were wrongly placed in the
unexplained category, as they are correctable abnormalities that are
unfortunately missed by routine pelvic examination and imaging
procedures. The present study also indicates that the tubal patency
plays a major role in conception and evaluation by laparoscopy
along with chromopertubation, giving a better idea regarding the
cause and management of the condition. This study reinstated the
age-old theory that HSG and laparoscopy are complementary to
each other and not a supplementary investigation in diagnosing
tubal factor of infertility. Needless to emphasize that it is a very
useful tool that can detect various structural abnormalities in the
pelvis, tubes, uterus, and feasible therapeutic procedures can be
done in the same sitting. When done by experienced hands with
a proper patient selection of patients, hysterolaparoscopy can be
considered as a definitive investigation and daycare procedure for
evaluation of female infertility and formulating a specific plan of
management.
